In many cultures throughout the world, mostly in developing countries, medicinal plants play an important role in the maintenance of people’s health. Despite this, some plants can be inherently toxic. People are not generally well-informed about this risk, and the concept that natural means safe prevails. Considering the associated risk of the misuse of medicinal plants, children represent an even more vulnerable group than adults. The main goal of this study is to evaluate the local knowledge of medicinal plants related to child care by mothers and care takers in a district of Criciúma, Southern Brazil. An ethnobotanical household survey was carried out with 42 mothers or care takers through open interviews, and botanical samples of the plants they used were gathered. The information collected about traditional knowledge was compared with references cited in Normative Instruction n°5 journal, and other scientific literature in order to evaluate similarities and differences. A total of 18 plant species were mentioned. Information on 83% of cited plants were found in the scientific references. 51% of therapeutic uses matched the literature guidelines. There was an absence of indications and restrictions for use with children for 34% of mentioned plants. The use of medicinal plants can be considered an important element in the maintenance of local knowledge and culture. This practice also represents an affordable therapeutic option, in communities where poverty and a lack of access to modern medicine are prominent factors. Just like other medicines, medicinal plants may have side effects however, and administration to children should be performed with careful attention.

Key words: Ethnobotany, local plant knowledge, medicinal plants, children.

INTRODUCTION

Throughout human history medicinal plants have been used in health recovery, and have evolved from simple household preparations to complex artificial forms (Lorenzi and Matos, 2008). Despite the growing development of public health policies around the globe, data from the World Health Organization (WHO, 2004a) estimates that between 1.3 and 2.1 billion people live without access to essential medicines, and that in many developing countries traditional medicine represents a key option for primary care for 70 to 95% of the population.
In 2006 the Brazilian Ministry of Health (MS), through the National Health Surveillance Agency (ANVISA) published the No. 5.813 Decree in order to ensure the safety, efficacy and quality of medicinal plants and herbal medicines, and promote their rational use by the Brazilian population. (BRAZIL, 2006a). Normative Instruction (NI) publication (No. 5 March 31st 2010 (BRAZIL, 2010) lists references used to evaluate the safety and efficacy of medicinal plants. This publication was used as a guideline to evaluate the local uses of medicinal plants cited in our research. These guidelines are not, however, applicable to the use of medicinal plants with children.

Even without specific Brazilian legislation for the use of medicinal plants in children, the ancient practice is still present among young mothers. The growing trend towards a more natural way of life has led to the increased use of medicinal plants in Brazilian society over recent decades, and consequently the use of phyto-pharmaceutical products augments modern medicine. In this setting, medicinal plants are generally considered low risk (Mengues et al., 2001), but this is a misconception because some plants can present adverse effects or even be intrinsically toxic. Furthermore, the misguided use of the wrong species in a traditional medicine, or the potential contamination of plant material by toxic substances such as metals and pesticides have the potential to increase the risks associated with medicinal plant use (WHO, 2004b). Given the growing use of herbal medicines and medicinal plants in Brazil and around the world, it is important to predict the inherent risks linked to the use of some plant species, since pharmacological effects can be noxious to a user’s health (WHO, 2002a). The Normative Instruction (NI) publication (n° 5, March 31st 2010 (BRAZIL, 2010)) lists references for use in evaluating the safety and efficacy of medicinally-relevant plants.

This publication was used as a guideline when evaluating the local uses of medicinal plants cited in our survey. Higher risks are clearly associated with the use of plants in children. Numerous physiological differences between children and adults, such as protein binding capacity and immature function of renal and hepatic systems, can be responsible for overdoses and other toxic events (Ginsberg et al., 2004; Rang et al., 2007). Brazilian law does not advocate the use of herbal medicines with children, but it is an ancient practice used by many mothers, influenced by the popular use of certain medicinal species. Considering the hypothesis of a higher risk associated with plants used in child care, and the importance of monitoring the safety of medicinal plants within traditional medicine systems, this survey aims to evaluate the knowledge of medicinal plants used in child care by mothers and care takers in a district of Criciúma, Santa Catarina State, Southern Brazil, and to compare the collected information with references cited in Normative Instruction (NI) no. 5 (BRAZIL, 2010) and other scientific literature, so as to analyse similarities and differences.

METHODS AND MATERIALS

Study area and group

Criciúma was founded at the end of the 19th century during the cycle of European immigration to Brazil. The first immigrant families were Italians coming from regions of Venice and Treviso. During the 1920s, the city experienced social and economic change due to coal exploitation. Nowadays, the estimated population is 202,395 inhabitants, and the main industrial activities include ceramics, coal extraction, textiles, metallurgy and plastic (IBGE, 2013). The study was conducted in São Roque, a district in the south of Criciúma (Santa Catarina, southern Brazil). São Roque is located at latitude 28° 41’ 45.63”S and longitude 49° 23’ 57.62”W, approximately 4 kilometres from Criciúma’s downtown (Figure 1). It has a population of 748 inhabitants divided into 142 households. The area consists of a moist tropical forest zone fragmented by agricultural fields (IBGE, 2004). Both the information and the call for participation were made through preliminary visits to district families. Interviews were conducted with mothers and care takers living in the district and who agreed to take part in the study, giving informed consent.

Ethnobotanical study

The study was carried out in March and April 2010 in accord with Resolution n°196/96 (National Health Council). Data collection consisted basically of interviews using a questionnaire designed by Martin (1995) with modifications. The research was approved by the Ethic Committee of UNESC (Universidade do Extremo Sul Catarinense) under Article n°95/2010. The questionnaire was designed to be anonymous, confidential, and to collect information on local knowledge of the plants used with children. Due to possible differences in the literacy levels of interviewees, it was decided that the questions would be asked verbally and that the answers would be filled in on the questionnaire by the interviewers. The interviews were carried out in participant’s homes and lasted as long as the participant found necessary.

Botanical material

During the interviews, medicinal plants cited in the survey and available near the interview sites were collected in order to conduct plant identification. Some interviewees reported using plant material purchased at local herbalists and pharmacies. In this case, when plant material was in the appropriate condition a sample was collected for later plant identification. When this was not possible, the plant nomenclature presented on the packaging was assessed. In this case, only plants produced by registered industries (in agencia Nacional de Vigilância Sanitária - ANVISA) were considered. Plant specimens were identified by botanical specialist Dr Vanilde Citadini Zanette, and sample specimens were deposited at the Herbarium Padre Dr. Raulino Reitz of UNESC-Criciúma.

Data analysis

In order to evaluate the knowledge of medicinal plants used in child care by mothers and care takers from the São Roque district, the information collected was compared with references cited in the NI publication.
The origin of their knowledge and the majority reported that the information was passed down from their parents, grandparents, elderly people or friends, through oral communication. Few interviewees reported knowledge being obtained using pertinent literature or through the Catholic Church’s Health Pastoral (CCHP) informers. Concerning the use of plants with their children, 92.8% (n=39) of participants reported such use at least once. The other 7.2% (n=3) declared the non-use of plants due to children’s reluctance towards infusions or decoctions and also due to preferences for synthetic medicines which were perceived as more effective. Of the number of interviewees who reported using medicinal plants with children, 38% (n=16) described their association with synthetic drugs, and from this total, only 45.2% (n=19) acquainted children’s physician about this association. Moreover, 90.4% (n=38) of interviewees had never received any instructions from health professionals concerning the use of medicinal plants in children’s care. Table 3, shows plants used by participants, including their botanical and vernacular name, the plant parts commonly used, their preparation, traditional use and references corroborating traditional use in adults and in children. Matricaria chamomilla L. (Asteraceae), Pimpinella anisum (Apiaceae), Mentha piperita (Lamiaceae) and Melissa officinalis L. (Lamiaceae) were the most frequently cited species (data not shown).

DISCUSSION

According to the World Health Organisation (WHO, 2002a), traditional medicine, especially herbal medicine, is widely used around the world. In South America, medicinal plant use is linked to historical circumstances, cultural beliefs and socioeconomic factors. The research participants mostly consisted of people who had attended

Plant part(s) used: Lv-leaves, Fl-flower, Fr-fruit; 1-Plant material purchased at a pharmacy or herbalist, no voucher available.
attended high school or secondary school. This data is similar to that described by IPEA (2013) noting the municipality of Criciúma as a range of educational human development. According to the IPEA (2013), the fastest growing city in absolute terms was education, and this is reflected in the district of São Roque. According to the literature, cultural and educational aspects influence the selection and use of medicinal plants (Arnous et al., 2005). In developed countries, the use of herbal or other complementary therapies is prevalent, and in recent years, this has also been seen in Brazil (Brasileiro et al., 2008). The survey of São Roque households revealed that leaves are the plant parts mostly used (94.4%) in medicinal preparations. This preference can be explained by the fact that leaves are generally available throughout the year and in subtropical regions can be collected without inhibiting plant growth and reproduction (Franco and Barros, 2006). Decoctions (63%), followed by infusions (37%) were the modes of preparation most reported during the interviews. Medicinal preparations such as infusion and decoction are commonly used by people due to easy preparing process. This kind of medicinal preparation contributes to body water balance and consequently to body temperature homeostasis and toxin depuration (Simões, 2007).

In the São Roque district, local knowledge and practice in plant use is orally transmitted from generation to generation and, less frequently, through written records. Oral transmission is generally the predominant way to disseminate traditional knowledge, but nowadays the accelerated process of modernisation is a threat to this teaching process. The fact that some interviewees reported keeping information on medicinal plants through written records is important, in that it allows the preservation of local traditions and makes the process of knowledge sharing easier. The availability of this data also can be connected with a better understanding of benefits and risks associated with the practice of traditional medicine (Leonti, 2011; WHO, 2011). Few participants (n= 4, 9.5%) reported preferring conventional drugs to the use of medicinal plants with their children. According to participants, conventional drugs are more effective, since the therapeutic effects can be seen faster during the treatment. This could be explained by the fact that therapeutic effects from herbal medicines and medicinal plants treatment are based on the synergistic and additive effects of a vast array of chemical constituents, with an efficacy that can be better seen only two or three weeks after the first administration (Barnes et al., 2007; Schulz et al., 2000). Several studies point to the use of medicinal plants as a therapy form for several populations. Some of the interviewees use medicinal plants with conventional drugs to treat children’s ailments without notifying their children’s physician of the practice. This lapse is probably not a deliberate act, but because plants contain mixtures of bioactive compounds, precaution must be taken in mixing herbal components and conventional medicines. Medicinal plants and conventional drug combinations are not recommended, simply because plants can interfere with drug pharmacokinetics (Griffin and D’Arcy, 1997). The risk of herb-drug interactions is exemplified in studies with garlic. Results have shown that bioactive compounds from garlic (Allium sativum; popularly known as Alho) in a dose-dependent manner could exert anticoagulant effects and affect haemostatic balance (Chan et al., 2007; Steiner and Li, 2001). In this context, patients using warfarin, for example, should be aware of the increased risk of bleeding associated with excessive garlic ingestion (Alexandre et al., 2008; Chavez et al., 2006). Analysing São Roque’s survey, we could see that only a fraction of interviewees (n=5, 11.9%) reported receiving information on medicinal plants directly from a health professional. Considering the risks associated with the use of medicinal plant-drug combinations, the advice of health professionals is essential for safety in medicinal plant use since they are able to correlate diverse areas of knowledge and thus promote rational use, and enable the use of selected plants in a science-based approach (Barnes et al., 2007; Oliveira et al., 2012). Health professionals should be encouraged to seek training in this area of knowledge for the purpose of educating the public in the use of medicinal plants.

Research showed that some interviewees, in some instances, obtained information about medicinal plants used in child care from informers of the Catholic Church’s Health Pastoral. CCHP informers represent a source of traditional knowledge transmission in southern Brazil (Neumann et al., 1999). This can be explained by looking back in time, when Jesuit missionaries came to help colonise Latin America. Their ability to collect the appropriate information and natural knowledge from indigenous people led the Catholic Church to dispense a wide range of traditional knowledge, placing this organisation at the centre of local knowledge transmission (Harris, 2005; Murray et al., 2011). Even if, historically, traditional medicines are used extensively all over the globe, in many countries the non-existence of regulated use or lack of access to accurate information leads to difficulties in the recognition and validation of traditional practices. Consequently health professionals tend to avoid the use of traditional medicines (WHO, 2000, 2011). Brazil has recently published new public policies specifically related to medicinal plants and traditional medicines so as to regulate, but also promote and encourage the correct use of herbal medicines (BRAZIL, 2006a, 2006b; Carvalho et al., 2010; WHO, 2011). These policies include the previously cited NI (BRAZIL, 2010), which lists the references required to evaluate the safety and efficacy of medicinal plants. This publication was used as guideline to evaluate the local uses of medicinal plants cited in our research. Of the total number of species cited by interviewees in this study, 83% were present in the references cited in the NI no. 5 and in other scientific literature, and
of infusion could have some effect on the colic pain, as simple abdominal massage. On the other hand, the phytochemical composition of *C. sinensis*, mostly the presence of caffeine, is certainly not indicated for the treatment of anxious states. Caffeine has a central stimulating effect and its intake can lead to symptoms such as restlessness, irritability and sleeplessness (PDR, 2007). Paradoxically, recent studies show that L-theanine, an amino acid also found in *C. sinensis*, exerts the opposite pharmacology and could be responsible for the anxiolytic effect reported by participants (Wise et al., 2012; Yoto et al., 2012). Daily ingestion of a *C. sinensis* decoction, by children whose diet does not include sources of haeme-derived iron, can also induce changes in iron absorption and thus lead to the development of microcytic anaemia. Its consumption should thus be limited in these populations, or food intake should be adjusted to include haeme-derived iron sources (Merhav et al., 1985; PDR, 2007; Srichairatanakool et al., 2006; Temme and Van Hoydonck, 2002). Concerning *Mentha piperita* (*popularly known as hortelã*), participants reported the use of an infusion/decoction from plant leaves to treat cough and cold conditions, as well as a vermifuge medicine. The treatment of common cold symptoms by *M. piperita* is well described in pharmacopeias and traditional systems of medicine (Blumenthal et al., 2000; WHO, 2002b), whereas its vermifuge action is poorly documented. Recent in vitro studies demonstrate that *M. piperita* essential oil is active against *Echinococcus granulosus* (Maggiore et al., 2012). In addition, some precautions must be taken when using *M. piperita* in children, mostly preparations containing the essential oil, that should not be topically used (in the nasal area) in infants due to the risk of glottal or bronchial spasm induced by possible hypersensitivity reactions (Vanaclocha and Cariguelar, 2003; PDR, 2007).

*Dysphania ambrosioides* (L.) Mosyakin and Clements (*popularly known as erva de Santa Maria*), and its chief constituent ascaridole, possess anthelmintic properties well described in literature (BRAZIL, 2006c; PDR, 2007), nevertheless the toxicity associated with this plant shows that it should be used cautiously, with children. *In vitro* genotoxic effects of the *D. ambrosioides* (L.) decoction and infusion have been recently reported (Gadano et al., 2002), furthermore, central nervous system disorders can also occur even with a therapeutic dosage of this plant. Taken together, these findings reveal that risks and benefits must be seriously balanced before using *D. ambrosioides* (L.) preparations (PDR, 2007; Tôrres et al., 2005). Approved indications of *Melissa officinalis* L. (*popularly known as Erva-cidreira*) include nervousness and insomnia, both symptoms associated with anxiety disorders, and also as a carminative for gastrointestinal disorders (PDR, 2007; WHO, 2002b). However, its use for treating cold conditions is not corroborated by scientific references. Concerning *Achyrocline satureioides* (Lam.) (*popularly known as marcela do campo*)
found to use a total of 18 plants belonging to 11 distinct botanical families for child care. The plants most cited were *Matricaria chamomilla* L., *Pimpinella anisum*, *Mentha piperita* and *Melissa officinalis* L. Decoction and infusion were the preferred preparation modes and the leaves were the plant parts prevalently used. Data revealed that 92.8% of respondents used plants for treating children’s illnesses. Only one-third of plants cited by participants possessed references corroborating their use in child care. On the other hand, this data emphasizes the importance of preserving and validating local knowledge and traditional practices on a risk-devoid basis. Even if carers seem to have access to, and do not reject conventional medicine, their cultural values and personal beliefs are important factors in the use of local herbal medicines. The need to promote their children’s health in an independent way can be proposed as an explanation for these local habits. Further studies are necessary to better understand local plant knowledge in order to prove its efficacy and safety in children care. Mothers and carers from the district should be assisted in choosing plants with demonstrated validity in child care. Public education measures are also necessary to fight the idea that ‘natural’ means ‘safe’ and the dangerous assumption that concomitant use of plants and conventional medicines is devoid of any risk.
